Week - 7

- String :- A string is text in python.
  It can contain letters, numbers, spaces, and symbols. Strings are written inside quotes.

eg:

```
name = "Aryan"
number_as_text = "123"
```

Note :- 123 is a number, but "123" is text.

1. Changing capital and small letters

- lower() - make all letters small

eg:- name = "ARYAN"

```
print(name.lower())
```

→ aryan

- upper() - make all letters small

eg:- name = "Aryan"
print (name.upper()).
→ ARYAN

- title() - make the first letter of each word capital

eg:- course = "python programming"
print (course.title()).
→ Python Programming

2. Removing extra spaces :-
Text can have unwanted spaces at the beginning or end.

- strip() - remove spaces from both ends

text = " hello "
print (text.strip()).
→ hello.

- lstrip() - remove spaces from ~~both ends~~ the left

print (text.lstrip())

→ hello

- rstrip() - remove space from the right

print (tat.rstrip())

→ hello

Tip: strip() is very usefull when reading ~~text~~ typed by a user or loaded from a file.

3. Finding text

in - check if txt exists.

eg:- email = "student@example.com"

print (word.find("gram")

→ 3

print (word.find("xyz")). (Note:- It always shows -1 if any chorat is not there.)

→ -1

positions start at 0.
If the text is missing, find()
gives -1.

- startswith() and endswith()

```
filename = "report.pdf"
print(filename.startswith("report"))
```

⟶ True

```
print(filename.endswith(".pdf"))
```

⟶ True

4. Replacing Text :-

- replace(old, new) changes one piece of text into another.

```
sentence = "I like Java"
new_sentence = sentence.replace("Java", "python")
print(new_sentence)
```

⟶ I like Python

It replace all matching occurrences. The original string does not change unless you save the result.

5. Splitting text into a list
- split() breaks one string into smaller pieces and returns a list.

Split by spaces

```
line = "red blue green"
words = line.split()
print(words)
```

→ ~~['Ali', '18', 'Dubai']~~ ['red', 'blue', 'green']

Split using a chosen separator

```
record = "Ali;18;Dubai"
parts = record.split(";")
print(parts)
```

→ ['Ali', '18', 'Dubai']

limit the number of splits

```
text = "one-two-three-four"
print(txt.split("-", 1))
```

→ [one, two-three-four]

use split() when several values are stored together in one line.

6. Joining text

.join() does the opposite of split():
It joins list items into one string.
The separator comes before .join()

```
word = ["red", "blue", "grun"]
print(",".join(words))
```

→ red, blue, grun

```
print("-".join(words))
```

→ red-blue-grun.

The list items must be strings.
Convert numbers using str()
before joining:

7. F-strings

An f-string lets you put variable values inside a sentence. put f before the quote and variables inside curly braclats.

```
name = "Aryan"
age = 20
print(f"My name is Aryan and I am 20
print(f"My name is {name} and I am {age}.")
```

→ My name is Aryan and I am 20.
